

Instance Data Replication

Instance Data Replication (IDR) copies data updates from one instance to one or more other instances. IDR provides a one-to-many replication, which enables one instance to propagate data across different departments and business units to keep data in sync.

Advantages of implementing IDR

- Simple: No-code configuration
- Flexible: Supports a variety of use cases
- Reliable: Minimal impact on performance
- Secure: Never leaves ServiceNow datacenters

Key features

- Copies data updates from one instance to one or more instances
- Maintains consistent data across different organizations in your company
- Enables one instance to propagate data across different departments and business units to keep data in sync through one-to-many replication
- Allows the modifying of data during replication to transform the data as applicable

Important considerations for instance strategy

- Instance to instance data integration is closely related to the instance strategy, single/ multiple instances
 - The instance strategy should be defined before instance data integration
 - Consider the question "Why are multiple instances needed and how do they fit in the target enterprise architecture?"
 - Be aware of the risk of instance 'crawl'; multiple instances make it more difficult to pursue a 'platform of platforms' strategy to seamlessly integrate enterprise workflows

QUICK REFERENCE GUIDE

When not to use IDR

Do not use IDR when your customer needs to:

- Move very large data sets: IDR is not a replacement for cloning, seeding limit is 3M records.
- Move data on a pre-set schedule: IDR syncs data in near real-time for targeted tables & columns.
- Move metadata: configuration, settings, etc., are not included with replicated data sets.
- Replicate data outside of ServiceNow: IDR does not support integration or data export use cases.
